MS lesions in the brain. The FLAIR technique is a T2-weighted sequence with a long TR and TE and is used to demonstrate the changes in T2 relaxation times in lesions when compared to normal tissue. As the name indicates, the signal of cerebrospinal fluid (CSF) is attenuated. CSF has a long T1 relaxation times compared to the other tissues in both the brain and cervical spine. Therefore, a rather long inversion time is needed to null the signal of CSF (~2500 ms). Hence, the contrast in T2-weighted FLAIR images allows for easier assessment of (MS) lesions, especially when the lesions are close to CSF, as compared to normal T2-weighted images. However, while the FLAIR technique works well in the brain, it is hampered by flow and motion artifacts when used in the cervical spine.

Double Inversion recovery

The Double Inversion Recovery technique has been implemented in the SPACE-DIR sequence in the Siemens syngo MR D13 software. A protocol optimized for brain imaging is also provided. SPACE-DIR is a T2-weighted technique which uses two inversion pulses, combined with a fat saturation pulse, to null both the signal of CSF and normal white matter. Similar to the FLAIR technique, this sequence is used to exploit the changes in T2 relaxation times in lesions when compared to normal tissue. In the brain, SPACE-DIR improves visualization of MS lesions in the brain. The FLAIR technique is a T2-weighted sequence with a long TR and TE and is used to demonstrate the changes in T2 relaxation times in lesions when compared to normal tissue. As the name indicates, the signal of cerebrospinal fluid (CSF) is attenuated. CSF has a long T1 relaxation times compared to the other tissues in both the brain and cervical spine. Therefore, a rather long inversion time is needed to null the signal of CSF (~2500 ms). Hence, the contrast in T2-weighted FLAIR images allows for easier assessment of (MS) lesions, especially when the lesions are close to CSF, as compared to normal T2-weighted images. However, while the FLAIR technique works well in the brain, it is hampered by flow and motion artifacts when used in the cervical spine.
the cortex and reveals cortical lesions as hyperintense relative to normal surrounding gray matter. It also provides a high contrast between white matter lesions and the surrounding normal white matter. Initial studies have investigated the applicability of DIR for lesion imaging in the spinal cord with positive results [3]. Nevertheless, while SPACE-DIR provides a high contrast and isotropic voxels, its rather long acquisition time (~8 min) may prove challenging within a clinical setting.

**T1-weighted phase sensitive inversion recovery**

A promising potential alternative for imaging MS lesions in the cervical spinal cord [4], is the T1-weighted true or phase sensitive inversion recovery (PSIR) sequence. This technique has been used to detect MS lesions both in white and cortical gray matter in the brain [5, 6]. This sequence exploits the differences in T1 relaxation times of tissues rather than the differences in T2 relaxation times as for both FLAIR and SPACE-DIR. Since the inversion time used is chosen such that it nulls the signal of normal white matter (~350–400 ms @ 3T), normal white matter is displayed as intermediate gray. All other tissues will have either lower or higher signal intensity than normal white matter depending on their T1 relaxation time relative to normal white matter. This provides a high contrast between MS lesions and surrounding tissue. Moreover, because PSIR uses a short TE, it is less sensitive to flow artifacts. High resolution imaging can also be achieved within reasonable scan times.

Based on these advantages, T1-weighted PSIR is now being explored for the detection of MS lesions in the cervical spinal cord.

**Reconstruction methods**

The T1-weighted PSIR images can be reconstructed as a magnitude or a phase sensitive (real) image (Fig. 1).

**Magnitude reconstruction**

The magnitude reconstruction does not consider the sign of the signal. Therefore, the tissue which is nulled by the inversion time will have a signal intensity of zero and all other tissues will have higher signal intensity (ranging from 0 to +4096), regardless of whether they have shorter or longer T1 relaxation time than the nulled tissue (Fig. 2). However, there is a range of inversion times where the contrast between two different
tissues, e.g., lesion and normal tissue, can be decreased or even disappear. This range depends on T1 relaxation times of the two tissues and range between the two inversion times that would null one or the other tissue. In the example shown in figure 3, it ranges from approximately 390 to 430 ms. An example of the magnitude image is shown in figure 4A.

**Phase sensitive reconstruction**

In the phase sensitive reconstruction, the sign of the signal is taken in account for the reconstruction of the image (Fig. 5). As opposed to the magnitude reconstruction where the signal intensity in the image ranges from 0 to +4096, for the phase sensitive reconstruction it ranges from -4096 to +4096. This results in an image where the tissue which is nulled by the inversion time will be displayed as intermediate gray and all other tissues will have a lower or higher signal intensity depending on their T1 relaxation times relative to the T1 relaxation time of the nulled tissue. Tissues with a shorter T1 relaxation time will have a higher signal (e.g. fat), whereas tissues with a longer T1 relaxation time will have lower signal (e.g. CSF). Unlike the magnitude reconstruction, the contrast between tissues remains largely preserved independent of the chosen inversion time. Since the T1 relaxation time of lesions might vary from patient to patient and even from lesion to lesion, the phase sensitive reconstruction should be used to reconstruct the images. An example of the phase sensitive reconstruction is shown in figure 4B.

**Clinical Cases**

**Case 1**

Patient with a MS lesion at the level of C6 (Fig. 6). The lesion is difficult to see on the T2- and PD-weighted images. However, the MS lesion can be clearly seen in the T1-weighted PSIR image.

**Case 2**

Patient with diffuse MS lesions in the spinal cord from level C3 to C6 (Fig. 7). The lesions are hardly visible on the T2- and PD-weighted images, whereas the T1-weighted PSIR shows the lesions more clearly.
Case 3
Patient with a known MS lesion at the level of C3-C4 (Figs. 8 A–C) and C7-T1 (Figs. 8 D–F). The lesion at the level of C3-C4 can hardly be seen on the T2-weighted image. Both the PD- and the T1-weighted PSIR show this lesion clearly. While the lesion at the level of C7-T1 is poorly visible on the T2- and PD-weighted images, the T1-weighted PSIR shows it very clearly.

Imaging Parameters
The parameters for the sequences used in the clinical cases are listed in Table 1.

Conclusion
The T1-weighted PSIR shows great potential in revealing MS lesions in the cervical spinal cord. While using this technique it is important to use the phase sensitive reconstruction to preserve the contrast between MS lesions and normal appearing tissue. Due to the nature of the reconstruction, and because T1 values of lesions can vary from patient to patient, for reliable depiction of lesions, the phase sensitive reconstruction is recommended. This is as, unlike the magnitude reconstruction, the phase sensitive reconstruction provides a contrast between different tissues that is largely independent of the chosen inversion time.
